S1.1. Sample preparation

Individual origami structures that were not destined to be mixed with other structures were prepared by a protocol similar to that presented in earlier work. Single-stranded M13mp18 DNA (scaffold strand) was purchased from New England Biolabs (Catalog # N4040S) and staple strands were obtained unpurified from Integrated DNA Technologies in water at 150 μ M each. Scaffold strand and staple strands for each design were mixed together to target concentrations of \sim 2 nM and \sim 75 nM, respectively, in 1 \times Tris-Acetate-EDTA (TAE) buffer with 12.5 mM magnesium acetate (TAE/Mg²⁺). The mixtures were kept at 90°C for 5 min and annealed from 90°C to 20°C with a constant rate of -1°C/min.

To create origami chains with multiple bonds based on binary sequences (as shown in Fig. 2c of the main text), constituent origami were first annealed separately from 90°C to 20°C. Next, corresponding quencher strand mixtures for each origami (those that matched the edge staples used, see Section S2.6) were added (at 10 \times the edge staple concentration) to each origami mixture. Each of the solutions was kept at room temperature for 1 hr to ensure complete hybridization, and then they were mixed together, heated to 50°C, kept for 12 hr at 50°C, and then cooled to 20°C at a rate of -5°C/hr.

For the origami chain (A-B-C-D) and dimers (A-B, B-C, C-D) with shape complementarity (as shown in Fig. 3c,d), each origami mixture (scaffold + corresponding staples) was annealed separately from 90°C to 50°C (with a rate of -1°C/min), mixed together at 50°C, and kept at 50°C for 12 hr, then cooled to 20°C at a rate of -5°C/hr. The mixing operation was performed inside a temperature-controlled chamber (Coy Laboratory Products Inc.), to maintain the temperature at 50°C while the samples were transferred between test tubes.

S1.2. Atomic force microscopy

Samples for AFM imaging were prepared by depositing 5 μ l of the origami solution with 20 μ l of TAE/Mg²⁺ buffer onto freshly-cleaved mica (Ted Pella). In most cases, clean buffer solution was deposited first and the origami solution was added on top of it. (For concentrated samples we felt this procedure minimized spatial variation in the density of origami on the mica.) In cases wherein we were concerned that this procedure might distort data (i.e. for thermodynamic data, section S3) we pre-diluted the origami solution by 5-fold, and then deposit 25 μ l onto mica. AFM images were taken under TAE/Mg²⁺ buffer in Tapping Mode with a Nanoscope III Multimode AFM (Veeco Metrology Group, now Bruker AXS). Typically, we used silicon nitride cantilevers with 2 nm radius silicon tips as AFM probes (the “short, fat” A cantilever on SNL probes from Veeco, now Bruker AFM Probes).

Supplementary Note S2: Design details

S2.1. Design of binary codes for stacking bonds

S2.1.1. Design criteria for binary sequences

Figure S1. Issues in binary sequence design. (a) DNA sequence design must deal with the problem of undesired partial complementarity. A desired bond is at left, an undesired partial bond at right. Binary sequence design is analogous, as explained in the text. (b) A simple binary sequence that allows a full-strength, self-complementary incorrect bond; this sequence, while nonpalindromic, is not uniquely-orienting. (c) A binary sequence whose strongest partial bonds are only of strength 4; an example is shown at right.

The basic design criteria for binary sequences can be understood by analogy to criteria used for DNA sequence design (Fig. S1a). Consider a DNA strand with the sequence 5'-TAGCAGCAG-3'; it is fully complementary to (and hence would bind most strongly with) a strand bearing the sequence 5'-CTGCTGCTA-3' (Fig. S1a-left). However, the two strands also have a partially complementary subsequence of length five, and could bind (albeit more weakly) via this partial interaction (Fig. S1a-right). In general, when DNA sequences are designed, they are designed to *minimize* such undesired interactions—with themselves, with their complements, and with any other strands that will be present in solution at the same time. Simple algorithms for designing sequences use discrete criteria based on the maximal number of base pairs that occur in any partially complementary species. For example, an algorithm might be designed to find sequences that minimize this number. Partial bonds having the same number of base pairs but different sequences are not equal in strength, and so more sophisticated algorithms minimize the sequence-dependent binding energy of undesired interactions. Still more sophisticated algorithms use such binding energies to maximize the probability that the desired interactions form by considering the thermodynamic partition function.

Here, because we do not yet have a complete energy model for stacking bonds, we take a simple approach based on counting (and minimizing) the number of active patches involved in the strongest partial bonds. For example, consider an origami with the binary sequence '111111100000'; with its complementary partner it would form a stacking bond of strength 7 (Fig. S1b-left), but when rotated it can

also form a self-complementary, undesired interaction of strength 7 (Fig. S1b-right). In contrast, the sequence ‘100100110111’ binds its complement (Fig. S1c, left) with a strength-7 bond, but the strongest possible partial bond that it can form has only strength 4 (Fig. S1c, right).

As for DNA, we are interested in minimizing such undesired interactions. For binary sequences of length l and number of active patches p , we wrote a program that enumerates sequences which have a maximum strength i for incorrect partial bonds (the mismatch constraint) with themselves and with their complements. Conceptually, the program compares each sequence to itself (and its complementary sequence) at all possible alignments, by “sliding” the sequences relative to each other; the number of matches for each alignment is simply counted and the sequence is discarded if the number of matches exceeds i for any alignment.

The set of sequences enumerated for a given (p,i) constituted a *candidate set* from which we later attempted to construct maximal orthogonal subsets for use in making origami chains (see Section S2.3). It turns out that for $p=7$, and $l=12$ or $l=16$ (the length of the sequence applicable to the regular and tall rectangles used in our study, respectively), the candidate sets are empty for mismatch constraints $i<3$. That is, *however* we design a binary sequence with 7 active patches (for $l=12$ or $l=16$), such a sequence will have an undesired partial bond (with itself or its complement) involving at least 4 active patches. More generally, for all p there exists at least i for which candidate sequences can be found. As i is made larger, the size of the candidate set increases; this holds true for the size of the maximum orthogonal subsets as well. Thus there is a tradeoff between the mismatch constraint i (our heuristic surrogate for the experimental specificity) and the number of distinct sequences available as bond types. This can be seen in Table S1 of section 2.1.3. Note that the minimum possible i is 2, since any pair of active patches in a binary sequence belongs to a partially self-complementary subsequence with at least two active patches.

S2.1.2. Example binary sequences

For the 12-patch system with 7 active patches, a total of 98 different binary sequences were found to satisfy the mismatch constraint $i=4$; for the 16-patch system with $(p,i) = (7,4)$, a total of 4614 sequences were obtained. We give some examples from each candidate set below. Full candidate sets are available upon request (woo@dna.caltech.edu); alternatively, one can generate the sets easily using the program code (attached as a separate Supplementary file).

12-patch system (10 examples shown,
out of a total of 98):

```
0 1 0 0 1 0 1 1 0 1 1 1
0 1 0 0 1 1 0 0 1 1 1 1

```

S2.1.3. Why use 7 active patches with a mismatch constraint of 4?

Our goal was to create the largest binary code that we could, with the largest number of distinct bond types, subject to the constraint that the bonds would have high specificity (that is, the rate of incorrect partial bond formation would be low.) We wrote a program to enumerate candidate sets for two different sequence lengths, a variety of different numbers of active patches, and mismatch constraints. We further used randomly seeded greedy search (see Section 2.3) to find the largest orthogonal subsets that we could for each candidate set. Table S1 summarizes our results. We found that choosing the parameters (p, i) to be (7,4), (8,5), or (9,6) with $l=16$ yielded orthogonal subsets with more than ten sequences, while still maintaining a reasonably large energetic difference between full-strength correct bonds and partial incorrect bonds.

		Total # of available patches = 12 (regular rectangle)					Total # of available patches = 16 (tall rectangle)					
		# of active patches, p					# of active patches, p					
		5	6	7	8	9	5	6	7	8	9	10
# patches i in partial bonds	2	4 (1)					320 (3)	0				
	3	214 (2)	0	0			1866 (27)	236 (6)	0	0		
	4		420 (15)	98 (2)	0			6520 (68)	4614 (12)	462 (2)	0	
	5			384	8 (1)	0			8322	2730 (13)	36 (2)	0
	6				328	14 (1)				6400	5870 (15)	496 (3)

Table S1. Size of candidate sets and the largest orthogonal subsets found as a function of sequence length, number of active patches, and mismatch constraint. Numbers in parentheses indicate the size of the largest orthogonal subset found (See Note S2.3). Shaded areas indicate the systems with 3-patch difference between full-strength and partial bonds (corresponding to an equilibrium ratio of $e^{-3\Delta G_p/kT}$, where ΔG_p is the free energy of a bound active patch and is equal to 2 times ΔG_{st} , the free energy of a stacked helix). Blank spaces indicate that the search process was not performed for the corresponding parameters (because the result would either be meaningless [$i \geq p$] or not useful, since either no candidate sequences would be found, or i was too close to p for bonds to be specific).

If one assumes the simplest model of binding energy for binary sequences (namely that the binding energy is linear in the number of active patches involved in a bond) then the energy of a full correct bond is $p \cdot \Delta G_p$ (where ΔG_p is the free energy of a bound active patch and is equal to 2 times ΔG_{st} , the free energy of a stacked helix), the energy of the strongest partial bond is $i \cdot \Delta G_p$ and the equilibrium ratio between the full correct bond and the strongest partial bond is: $e^{-(p-i)\Delta G_p/kT}$. A full treatment of the total error rate associated with a particular binary sequence would take into account not only the energy of the strongest partial bond, but also the number (multiplicity) of the different partial bonds having this energy, as well as the energies and multiplicities of all weaker partial bonds; such a treatment would calculate the full partition function for the system. Instead, here we simply assume that the multiplicity of the strongest partial bonds for different sequences is roughly the same. Given these assumptions then the equilibrium error rates for sequences from the three different systems—(7,4), (8,5), and (9,6)—should be the same. However, because the fraction of correct bonds versus unbound origami should increase with increasing p it would make sense to choose sequences from the system with full bonds of higher strength, *i.e.* a (9,6) system.

To check our assumptions about error rates, we measured the error rates for sample sequences from the (7,4), (8,5), and (9,6) candidate sets for length 12 sequences. Experiments analogous to those shown in Fig. 2a in the main text were conducted; Fig. S2 shows representative AFM images for each sequence tested. ‘L’-shaped labels on the origami made scoring correct head-to-tail bonds (L-L) easy; incorrect bonds included both bonds with rotated orientation and bonds with head-to-tail orientation that were misaligned. Surprisingly, the (7,4) sequence gave the best error rate, with the highest fraction of correct bonds out of total bonds—96.8% (N=344, for the sequence occurring in the bottom of Fig. S2a). The other systems performed considerably less well, with the (8,5) sequence having 77.7% correct bonds (N=358, Fig. S2b) and the (9,6) sequence having 52.7% correct bonds (N=277, Fig. S2c).

Figure S2. Comparison of sequence performance as a function of the number of active patches. A binary sequence and its complement are placed on opposite edges of an origami such that it should form long chains; each origami carries the label ‘L’. Full-strength correct bonds are measured by counting the bonds with head-to-tail orientation (L-L). Partial bonds of all types are also counted; they usually involve origami bound in the rotated orientation. (a) One (7,4) system, ‘100100110111’ (top) and another ‘010111100011’ (bottom). Error rate data were taken for the bottom system; the top system is included to show a high-res image of a system of qualitatively similar error rate. (b) An (8,5) system, ‘100101011111’. (c) A (9,6) system, ‘110111001111’. Scale bars: 500 nm.

This surprising trend might not be a general phenomenon, since just a few sequences were examined, or it could be the case that our assumption about the multiplicity of partial bonds is wrong and that, for example, the (9,6) sequence observed just had many more partial bonds than the other systems, all of them having the strongest possible strength (*i*). However, given our thermodynamic experiments (Section S3) another possibility suggests itself: that ΔG_p is not constant as the number of active patches p increases and thus the total stacking bond energy is not linear in the number of active patches. In particular, if ΔG_p decreases with increasing p then our results make sense. Then the energy difference between a full correct bond and the strongest partial bond in the (9,6) system is not as large as the analogous energy difference for the (8,5) system, which in turn is not as large as that for the (7,4) system. Such a sublinearity in stacking bond energy might be explained by steric interference or electrostatic repulsion between active patches, or it might be explained by a nonlinear bending energy term that increases as the use of more active patches results in them being more spread out and requires them to overcome a large-scale deformation of the origami. Because of the trends we observed in our experiments using sequences with constant p and i (Section S3, ΔG_p seems to decrease as active patches are more spread-out along the

origami edge) we suspect the latter hypothesis is a more likely explanation. Clearly performance measurements for many more sequences should be made, but based on these preliminary experiments, we chose to explore (7,4) sequences in the context of a longer, 16-patch system.

S2.1.4. Error rates for binary sequences investigated in this study

For edges of the tall rectangle system (which has 16 total available patches), there are 4614 different binary sequences with (p, i) of (7,4), as shown in Table S1. Within the set of those binary sequences, subsets (codes) can be found for which every pair of sequences from the subset is mutually orthogonal with the same matching criterion (no partial match between any pair of sequences involves more than 4 active patches). Our computer-aided search generated several codes of size 11 and 12; one code of size 12 and another code of size 11 were chosen for more detailed study. Each binary sequence from these codes was tested in the same way as in Fig. 2a, i.e., the binary sequence and its complement were placed on opposite edges of the tall rectangle, such that the rectangles form bonds in h2t orientation when the bonds are full-strength and correct. For each case, AFM data were analyzed and bond orientations were measured to obtain the ratio between the correct (h2t) bond orientation and the total number of bonds. The error rate measured for each binary sequence and an example of annotated AFM data from which such error rates are derived is shown in Table S2 below.

set	sequence #	sequence	% correct bonds	N
set1	1	0000010111100011	90.07%	423
	2	1110000011000101	84.39%	538
	3	0010000010110111	79.73%	301
	4	1100000010111001	86.50%	941
	5	0110101000100101	87.96%	191
	6	0100010100011011	97.55%	245
	7	1000100011010011	82.25%	524
	8	0111100100001010	96.53%	346
	9	1001001001100101	72.54%	142
	10	1110101001000010	87.64%	259
	11	1000010110010101	83.68%	337
	12	1101000100001101	83.36%	559
set2	1	0001011110001100	94.39%	659
	2	0010010011011100	78.07%	456
	3	1010010000110110	95.24%	210
	4	1000100010101101	74.29%	210
	5	0111000010110010	95.41%	827
	6	1100000010011110	95.54%	112
	7	1101010010000011	94.20%	448
	8	1001100101000101	91.67%	168
	9	1101000000110101	81.68%	475
	10	0110010110001001	78.33%	300
	11	1001101000100011	93.81%	113

Table S2. Error rates for stacking bonds made using binary sequences from two different sets (sequences within each set are orthogonal) and an example of AFM image analysis. Each bond was labeled and counted based on its orientation. The blue circles over the AFM image indicate bonds with the correct head-to-tail orientation and the yellow circular arrow indicates a single bond with an incorrect rotated orientation. The percentage of correct bonds (with h2t orientation) out of the total number of bonds analyzed (N) was recorded for each binary sequence. The AFM image is for binary sequence #3 in set2. Scale bar: 200 nm.

S2.2. Design of shape codes for stacking bonds.

S2.2.1. Design criteria for shape sequences

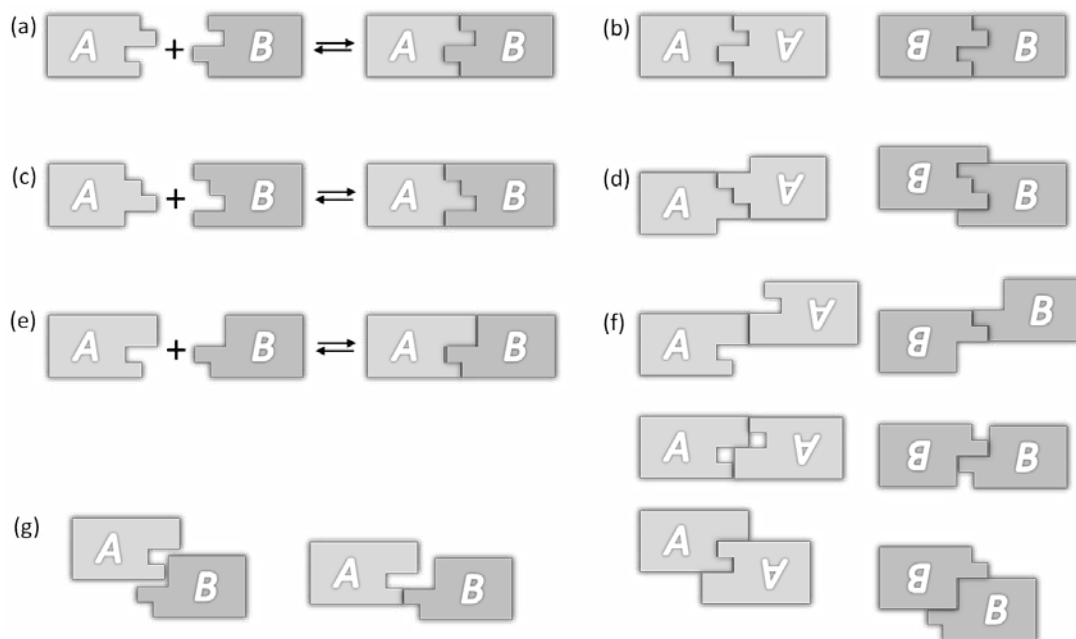

Figure S3. Examples of shape sequences and their partial bonds. (a) A 4-patch shape sequence could form a 4-patch bond between distinct origami, but because it is fully self-complementary (b) it also allows full-strength undesired bonds. (c) Another shape sequence and its complement could form a 4-patch bond, but (d) it also allows partially self-complementary 3-patch bonds (3/4 the strength of a full bond). (e) A shape sequence and its complement that we used between the **A** and **B** origami. (f) Examples of partially self-complementary (homogeneous) bonds of strength 2 for the sequences in (e). (g) Examples of partial bonds of strength 1 between the two distinct origami (heterogeneous) for the sequences in (e).

As in the design of binary sequences, the goal of minimizing undesired bonds dictates design criteria for shape sequences. As before, fully self-complementary sequences (Fig. S3ab) or partially self-complementary sequences (Fig. 3cd) must be avoided (unless a homodimer of origami is desired.) Computer enumeration of candidate sets of sequences for shape codes is essentially similar to that for binary codes, with two important differences. First, unlike the case for DNA or binary sequences, *not all shape sequences encode physically distinct bonds*; we discuss this in the next section. Second, unlike the case for DNA or binary sequences, *the program must make an extra check for the self-complementarity of the shape sequence's complement*. For DNA or binary codes, to evaluate whether a sequence should be a candidate sequence, it is sufficient to check that sequences' self-complementarity, and to check for any partial complementarity that it might have with its complement. This is because for a DNA or binary sequence, any self-complementary subsequence that occurs in the sequence implies the existence of a corresponding self-complementary subsequence in the sequence's complement, and vice versa. This is not the case for shape sequences: the shape sequence '100001' has a strongest self-complementary partial bond of strength 2, but its complement '011110' has a strongest self-complementary partial bond of strength 4. We note also that the minimum possible mismatch constraint i for shape sequences is 2 patches (as it is for binary codes), but this limit holds for a different reason in the case of shape sequences than for binary sequences. The reason is that, for an arbitrary shape sequence, the first two or last two

patches both form self-complementary subsequences that can bind to themselves without steric hindrance from any of the other patches (if the two origami carrying them are in a rotated orientation). The top two and bottom two examples in Fig. S3f demonstrate this phenomenon.

Early on in the project we thought we might achieve a large number of specific bonds through the use of a long ($l=6$ or $l=9$) shape sequences. Fitting these high complexity sequences into the relatively small area of an origami necessitated using patches that were just 2 helices wide. These proved too flexible to prevent bent-patch bonds (see S.2.7.1) so we decided to use 4-helix wide patches to implement shape codes. This restricted the length of the shape sequences we could use to just 4 patches; similarly we restricted ourselves to just three depths to avoid long, flexible patches. Fortunately, even with these restrictions, the candidate set for the mismatch constrain $i=2$ had 16 elements, which we discuss next.

S2.2.2. Full list of candidate shape sequences for the (4,3,2) system

Given the number of patches (p) and number of depths (d), our program searches the entire sequence space and examines the possible partial bonds for each shape sequence with itself, each sequence with its complement, and each complement with itself to see if they exceed the mismatch constraint (i). For $(p,d,i) = (4,3,2)$ the program generated a candidate set of 16 unique shape sequences, listed at left below. Note first, that if a sequence appears, its complement does not appear: our desire is to make a set of candidate sequences for distinct bond types and a sequence and its complement are *equivalent* with respect to the physical bond type that they encode. Similarly, sequences that are related by a simple *shift* in depth, such as '0010' and '1121' (Fig. S4ab), encode the same bond type and are thus equivalent. Only a single sequence from an equivalence class is included in the candidate set. Recall that due to stacking polarity, a shape sequence (e.g. Fig. S4a) and its reverse (Fig. S4e) are inequivalent, unless they are palindromic. (Shape sequences and their reverses are expected to be similar for some properties, e.g. flexibility.)

List of the 16 shape sequences:

- 1 '0010' (= '1121' = '1011' = '2122')
- 2 '0020'
- 3 '0021'
- 4 '0100'
- 5 '0102'
- 6 '0110' (B-C bond)
- 7 '0200'
- 8 '0201'
- 9 '0211'
- 10 '0220'
- 11 '0221'
- 12 '1020' (C-D bond)
- 13 '1120'
- 14 '1200' (= '2201', A-B bond)
- 15 '1220'
- 16 '2010'

(Equivalences are not exhaustively listed.)

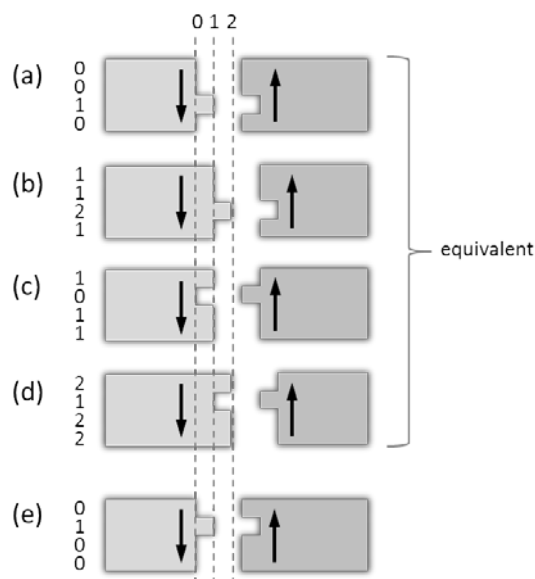

Figure S4. Equivalences between shape sequences. (a), (b), (c), and (d) are all equivalent with respect to the bond type they encode. Vertical arrows denote stacking polarity. (a) and (b) are related by a simple shift in depth, (b) and (c) are complementary, (c) and (d) are related by a depth shift, and (a) and (d) are complementary. (e) is, however, distinct from the others because it is the reverse of (a), and has opposite stacking polarity.

S2.2.3. Orthogonality graph for the (4,3,2) candidate shape sequences

Using our computer program, one can check the orthogonality between any two sequences in the set of 16 shapes listed in the previous section. By applying the same mismatch constraint for the strongest partial bonds ($i = 2$) between different sequences, the orthogonality relations can be determined for each pair of sequences (a total of 120 combinations). Fig. S5a shows the full orthogonality graph for all 16 shape sequences in the candidate set. Line segments between numbered circles indicate that the two shape sequences corresponding to the numbers are orthogonal to each other. (For the identity of each shape sequence, see list in the previous section.)

Sets of mutually orthogonal sequences correspond to *complete subgraphs* or *cliques* of the orthogonality graph. That is, a set of vertices for which *every* pair of vertices is connected by a line segment corresponds to a set of mutually orthogonal sequences. For example, one complete subgraph is the red triangle in Fig. S5b which corresponds to an orthogonal subset with three sequences, {6,12,14}. An exhaustive search confirmed that the size of the largest orthogonal subsets for the given system is 4 — for example the subset indicated by the red subgraph in Fig. S5c: {3,6,7,16}. We attempted to construct origami chains based on a subset of size 4. Unfortunately, the set we chose included sequence 5, which, along with its reverse sequence 16, turned out to be susceptible to the formation of bent-patch bonds. In the interest of saving time and money, and because we had demonstrated that sequence 6 worked well, we ended up choosing the 3-sequence subset {6,12,14} to explore as a shape code. The four sequence orthogonal subset {1,11,12,14} looks promising, but was not explored.

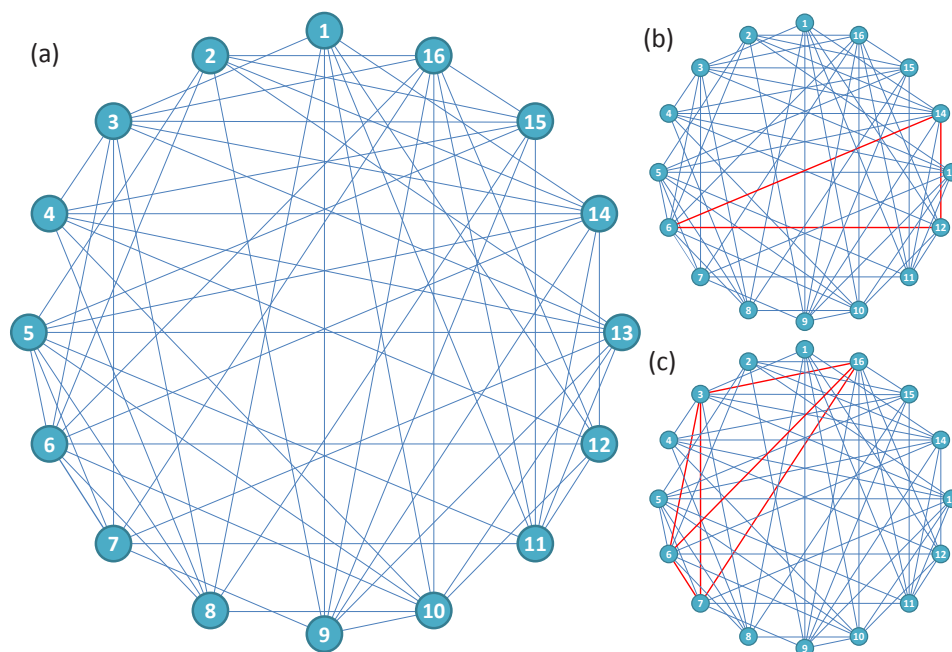

Figure S5. Orthogonality graph for the candidate set of 16 shape sequences. (a) The full graph. Each line connecting two numbered circles indicates that the two shape sequences are orthogonal. (b) Red triangle highlights an orthogonal set of size three with sequences 6, 12, and 14. (c) Red subgraph highlights an orthogonal set of size four with sequences 3, 6, 7, and 16.

S2.2.4. Size of shape sequence spaces with other parameters

In addition to the 4-patch system with $d=3$ and $i=2$, we explored other shape sequence spaces with different parameters, a couple of which were tested experimentally (some results are shown in Note S2.6.1). In the table below, we summarize the sizes of shape sequence spaces with various parameters (different numbers of patches, different numbers of depths, different numbers of patches allowed in incorrect bonds). In the right-hand column we report the size of the largest orthogonal subset discovered over the course of multiple random searches, as described in Note S2.3.

For parameters not included in this table, one can easily obtain the shape sequence space – not only the size but the entire list of candidate shape sequences – using the program code provided as a separate Supplementary file.

# patches (p)	# depths (d)	# patches allowed in incorrect bonds (i)	% patches in incorrect bonds	Size of shape sequence space	Size of largest orthogonal subsets found
4	2	2	50%	3	1
	3	2	50%	16	4
	4	2	50%	61	8
6	3	2	33%	5	1
		3	50%	49	7
	4	2	33%	145	6
		3	50%	423	22
9	3	2	22%	2	1
		3	33%	14	5
	4	2	22%	233	6
		3	33%	1113	25
	5	2	22%	6510	15
		3	33%	24791	60

Table S3. Sizes of shape sequence spaces and orthogonal subsets for different systems. The purple-shaded parameters are those for the shape sequences most explored by this study.

S2.3. Finding codes: searching for large orthogonal sets of sequences.

So far we have largely discussed, for both binary sequences and shape sequences, the symmetry and mismatch constraints that are required of a sequence for it to be useful as an individual stacking bond in isolation — constraints such that, with high probability, the sequence will bind its complement by a full correct bond rather than binding to itself or binding its complement by a partial bond. Given a set of parameters including the length of the sequence, number of active patches, the number of depths (if appropriate), and a mismatch constraint, we have shown that it is straightforward to enumerate all sequences that individually satisfy the constraints. Our two most studied examples are the 4614 binary sequences for $(p,i) = (7,4)$ and the 16 shape sequences for $(p,d,i) = (4,3,2)$. In order for such candidate sequences to be used in a multiple-bond system, one must find a subset that is orthogonal — that is, all pairs of sequences must satisfy the mismatch constraint. A diagram of the orthogonality relation between all 16 sequences in the $(4,3,2)$ shape sequence candidate set, and example orthogonal subsets are discussed and diagrammed in Section S2.2.3.

An important goal is to find the *maximal* orthogonal subset of a candidate set, to find a code of sequences that can support the largest diversity of stacking bond types. For candidate sets containing relatively few sequences, such as the $(4,3,2)$ shape sequences, an exhaustive search through all possible orthogonal subsets is possible. But for bigger candidate sets, the combinatorially large number of subsets makes finding the maximal orthogonal subset by exhaustive search a computationally intractable task.

More specifically, the problem of finding the maximal orthogonal subset is a trivial rephrasing of the well-known *Max Clique* problem in computer science. Max Clique is known to be NP-hard, and here two facts about NP-hardness are relevant: (1) Most computer scientists believe that NP-hard problems can only be solved exactly using an amount of time that is an *exponential* function of the size of the problem — this is what is meant by “computationally intractable”. (2) NP-hard problems can be approximated — thus while it might be computationally intractable to find the maximal orthogonal subset, it may be possible to find large subsets, which are close in size to the maximal orthogonal subset, quickly.

There is a large literature on approximating NP-hard problems, but we did not take advantage of such approximation techniques here. Instead, to quickly get large orthogonal subsets that we could use for multiple stacking bonds, we implemented a simple, randomly seeded, greedy search procedure. For many of the smaller candidate sets, the orthogonal sets we obtain are probably maximal; in the case of the $(4,3,2)$ shape code system we verified that this was the case. For larger candidate sets it is highly likely that the orthogonal sets we have obtained are not maximal; it might be possible that there exist 13-sequence orthogonal sets for the $(7,4)$ binary code system. For the moment, the orthogonal sets that we have found are satisfactory since we obtained orthogonal sets whose size roughly matches the maximum number of origami that we can handle easily, or can afford in the lab. However, if the need should arise, e.g. for much larger codes, many relatively fast algorithms for finding large cliques (and hence finding large orthogonal subsets) are available. One example is *Cliquer*, a set of C routines that are available for download from: <http://users.tkk.fi/pat/cliquer.html>

Our program for discovering large orthogonal subsets constructs them in a “greedy” fashion starting from single sequences from the candidate set. Let the size of the candidate set be N . Each run of our

program constructs N different orthogonal subsets, by sequentially using each one of the elements of the candidate set as a seed for a different orthogonal subset. The details of our program are as follows:

- (1) The program first picks one candidate sequence as a seed; that candidate sequence becomes the first element of the orthogonal set under construction.
- (2) The program randomly picks another sequence from the candidate set and checks its orthogonality with the existing element(s), with respect to the mismatch constraint i .
- (3) If the newly picked sequence is orthogonal to the existing element(s), it is added to the set; otherwise it is discarded.
- (4) The program repeats steps (2) and (3) until all candidate sequences have been tested for the orthogonality with the growing set. After all candidates have been tested, the orthogonal set is output.
- (5) The program repeats steps (1) through (4) until all candidate sequences have been used as a seed for an orthogonal set.

Since the construction of an orthogonal set is sensitive to the order of addition of candidate sequences (a different order results in a different set), each run of the program results in N potentially distinct orthogonal sets. Typically, we ran the program multiple times; we did not keep track of the number of runs performed. The largest orthogonal subsets found are recorded in Table S1 (for binary sequences) and Table S3 (for shape sequences).

S2.4. Design of the origami structures

Design of the rectangle systems (regular and tall) was performed based on the procedure described in the original DNA origami paper, using MATLAB code. Origami with edge shapes (A, B, C, and D origami) were designed using a modified version of the “square lattice” version of caDNAno. caDNAno software was customized to allow (1) the creation of single stranded loopouts in the scaffold strand and (2) the highlighting of the scaffold strand with a user-specified sequence (e.g. ‘GC’). Both features were added to facilitate the process of shifting the scaffold strand and aligning ‘GC’ on the edges. In our modified version of caDNAno, the ‘loop tool’ which is normally used to generate double-stranded loops (loops involving both the scaffold and staple strands) has been changed to a tool that creates single-stranded loops only in the scaffold strand. The highlighting feature has been integrated into caDNAno’s existing ‘add sequence’ function, with which a user can select the scaffold sequence to use; now a user can specify a sequence to highlight using the same dialog box (Fig. S6c). Color is fixed for each highlighted base: G-Green, C-Cyan (light blue), A-Amber (roughly orange), T-Tomato (red). The length limit for a highlighted sequence is set to be the same as caDNAno’s existing length limit for the scaffold sequence (20,000), so a user can highlight the entire scaffold sequence if desired. A few other minor modifications include: (1) skipping the step of waiting for the user to click on the 5’ end of the scaffold during an ‘add sequence’ operation if there is only one 5’ scaffold end in the design, and (2) updating the scaffold and staple sequences automatically after creating a new loopout (this automatic update works only after the scaffold sequence has been defined). The modified version caDNAnoSQ_SW is available as a separate Supplementary file (or by request to woo@dna.caltech.edu for latest version). For general instructions and the original version of caDNAno, visit <http://www.cadnano.org>.

Figure S6. Screenshots of a version of caDNAno modified to allow placement of ‘GC’ on origami edges. All occurrences of the sequence ‘GC’ are highlighted along the scaffold strand in the diagram by green and cyan for G and C, respectively. (a) One can count the number of bases from a blunt-end on the edge to the next occurrence of ‘GC’ and (b) make a single-stranded loopout inside the structure to *shift* the scaffold sequences. In the example design shown, the scaffold strand has been already aligned to have ‘GC’ along the edge [as shown in the zoom-in at (a)]. (c) Here we have shown highlighting of the sequence ‘GC’. One can enter any sequence to highlight at the step where user selects the scaffold strand.

S2.5. Edge structure

Because accurate models (backed by high resolution structural data) of origami edges do not exist, it is difficult to predict the exact structure and stacking configurations of the blunt-ends on the edges of origami. Here we provide gross predictions based on the distance of the blunt-ends from the nearest internal crossovers and the pattern of crossovers along the edge. We predict structures for three different edge models: (1) a *crossover-free edge* (Fig. S7a), (2) a *relaxed edge* with only scaffold crossovers (Fig. S7b), and (3) a *stressed edge* with both scaffold and staple crossovers (Fig. S7c). These predicted structures in turn make predictions about the expected strength and behavior of the stacking bonds.

For all three models we are interested in the helical twist of the base pairs on the blunt-ends at the edge, and for all three models we posit an internal crossover 16 base pairs interior to the edge. Here, we draw bars, separated by the major/minor groove angles, on the face of the blunt ends to indicate the helical twist of the base pair. To derive the orientation of these bars, we begin at the interior crossover and consider the strand that is “edgeward” of the crossover (e.g. the orange 3D strand in Fig. S7a). We model the two base pairs next to the crossover point as staggered up and down with respect to the midpoint of the crossover, having a helical twist angle that is rotated from the midpoint by $\frac{1}{2}$ of the characteristic rotation/bp of B-DNA ($\sim 34.6^\circ$ given 10.4 bp/turn) — that is approximately 17° . (Similar modeling is performed in Ref. 1.) From these “first edgeward base pairs” the base pairs at the blunt end are 15 base-pairs away. Thus the blunt end base pairs have a helical twist angle that is rotated $\sim 519^\circ$ ($15 \times 34.6^\circ$) relative to the bases of the edgeward strand in the crossover (in a clockwise direction when viewed from the blunt-ends towards the crossover) for a total of $\sim 537^\circ$ from the crossover midpoint. Given such a model, which is crossover-free at the edge, the base pairs at the blunt-end would be oriented like those depicted in Fig. S7a. We note that while we do not make such a structure in this work, origami with very similar crossover-free edges have been made before (Ref. 10 of the main text) using “tile adapters”, and so such structures can be experimentally synthesized.

Now consider a second origami with the same crossover-free edge structure, but with 15 base pairs between the edge and the crossover. When such an origami binds via a stacking bond to the origami described above, then the total number of base pairs between the first internal crossover points of the two origami will be $15+16 = 31$, or roughly 3 helical turns. This means that for such crossover-free origami, the blunt-ends on opposite sides of the stacking bond are oriented with a relative twist angle of $\sim 34.6^\circ$ (as depicted in Fig. S7d). Thus we would expect stacking of blunt ends between crossover free edges to be native B-form stacking, and that it should be relatively strong.

Next consider our second edge structure, the relaxed edges (Fig. S7b), for which scaffold crossovers connect every other pair of helices. This is the edge structure that we use in all our work on stacking bonds, (except for structures pictured in Fig. 1e of the main text and Fig. S14j-o). Because the scaffold crossovers act to pull the base pairs away from the helical twist angle that they would assume in a crossover-free edge, whatever structure forms at relaxed edges cannot be B-form DNA. However, because DNA can tolerate small deviations from B-form twist, we propose that the helices assume an amount of twist strain (roughly 34.6° , which is averaged over the 16 base pairs up to the crossover) and maintain native major/minor groove angles between the bases at the blunt end (as depicted in Fig. S7b).

Given our model for relaxed edges, when two origami with relaxed edges bind via a stacking bond, their blunt ends will not be able to stack via B-form stacking; rather, they should bind with slightly

different relative twist angles that are within approximately $\pm 34.6^\circ$ of the natural twist angle in B-DNA (Fig. S7e). We call such stacking between relaxed edges *near-B-form stacking*, which we predict would be roughly as strong as B-form stacking. Since relaxed edges have a top-bottom asymmetry that is defined by the major and minor grooves, near-B-form stacking can only occur when two origami bind in either the head-to-tail or rotated orientations. This prediction agrees well with the distribution of observed bond orientations, as discussed in the main text.

Finally, we consider the case of stressed edges. When staple crossovers are placed in opposition to scaffold crossovers along an edge, we propose that the balancing of the stresses they induce results in a near-flattening of the major and minor grooves (Fig. S7c). The resulting decrease in distinction between the major and minor grooves should decrease the distinction between the top and bottom of the origami. Therefore, we would predict that blunt-end stacking between such stressed edges (Fig. S7f) should allow flipped bond orientations; this is indeed what is observed in experiments involving origami with stressed edges, such as those shown in Fig. 1e of the main text and Fig. S14j-o.

Figure S7. Comparative modeling of three different origami edge structures. (a) *Crossover-free edges.* (b) *Relaxed edges* with only scaffold crossovers. (c) *Stressed edges* with both scaffold and staple crossovers. Each circle indicates a blunt-end. In (a), both the black and colored bars (inside the circles) indicate the helical twist of bases belonging to *tile adapter strands*. In general, tile adapter strands are strands that extend from the edge of an origami to give it a geometry that is not possible using the canonical scaffold/staple geometry. Here, our intent is that the tile adapter strands create a crossover-free edge; we do not show the details and did not use them in our stacking experiments. Here we use them as part of a “thought experiment” concerning the geometry of stacking bonds, but we note that tile adapter strands have been used to create origami with a very similar crossover-free edges (Ref. 10 in main text). In (b) and (c), black bars indicate the helical twist of bases from the scaffold strand, and colored bars indicate the helical twist of bases from the staple strands. Bars of the same color indicate the same strand, e.g., the orange staple in (a) runs for 1.5 helical turns in one helix, switches between helices at a 16-bp-deep internal crossover, and runs back for a length of 1.5 helical turns in the adjacent helix, as depicted by the 3D drawing. Black dotted arrows indicate crossovers at the edge. In all three models colored strands are intended to make 16-bp-deep internal crossovers. The models in (a-c), predict that the blunt ends on the edge are either B-form (a), near-B-form (b), or have disrupted base pairs that are incompatible with B-form geometry (c). (d-f) show models of the juxtaposition that occurs when two different origami edges form a stacking bond; these bonding models correspond to the edge structure models in (a), (b), and (c), respectively. Models (d) and (e) make predictions for the relative helical twist between blunt-ends across the bond. Model (f) suggests that the disturbance of the base pairs at the edge of the origami may decrease the distinction between the major and minor grooves enough to create a top-bottom pseudosymmetry. This pseudosymmetry could allow bonding between origami in one of the flipped orientations (not shown).

S2.6. Quencher strands

In a binary coded system in which multiple origami containing different binary sequences on their edges are mixed together, interference can arise between the edge staples used to set the sequences on one origami and the edges representing different sequences on another origami. This occurs because all origami in the binary coded system share the same basic design, and their edges share the same staple binding sites. For example, if one origami bears a sequence on its right edge that has a '1' in a particular position, then the staple that creates that active patch can bind to the *same* location on a different origami for which that location was intended to remain inactive, effectively "flipping" a '0' to a '1'. In the worst case, all of the origami would end up with exactly the same sequences, with the right edge of each origami encoding a sequence that represents the bitwise OR of all the sequences on the right edges of the original origami, and the left edge encoding an analogous bitwise OR of all the left-edge sequences. Prevention of such interference could be achieved by purifying the origami to remove excess staples *before* mixing the origami. But purification steps are usually accompanied by significant loss of the origami themselves and may incompletely remove staples. In particular, simple and fast methods such as spin filtration reduce excess staples only by a factor of 5- to 10- fold; more complete removal requires more stringent methods such as gel purification. Complete removal is important because, as we observed in tests of spin purification, relatively small and sporadic changes to edge sequences can significantly increase error rate. As an alternative approach, we introduced strands complementary to the edge staples, which we term *quencher*s.

Quenchers bind to the excess free edge staples in solution and effectively prevent them from binding to the scaffold strand. Quenchers were designed so that they have complementary sequences to the corresponding edge staples (thus quenchers have sequences derived from scaffold strand subsequences), and extra two thymine bases were added to both the 5'-end and the 3'-end (so that the quencher sequence becomes 5'-TT-staple complement-TT-3'). The thymine addition was done to minimize the potential influence of (1) stacking interference from blunt ends that would be generated if simple complements were used and (2) breathing of the resulting quencher-staple duplex that might allow the edge staple strand to bind to a '0' location anyway, via a branch migration process.

The efficiency of the quenchers at blocking the free edge staples was not explicitly measured. However, the high molar excess of the quenchers used (10× the concentration of edge staples) and the high free energy of binding between the quenchers and the edge staples (on the order of ~40 kcal/mol, calculated using Oligo Calc, <http://www.basic.northwestern.edu/biotools/oligo.html>) predicts the concentration of free edge staples, in the presence of the quenchers, to be extremely small — on the order of 10^{-21} nM. The experimental protocol for using quenchers is described in Supplementary Note S1, and the detailed sequences are given in Supplementary Note S5.

S2.7. Warnings

In case one wants to repeat or adapt some of our experiments, we give warnings that describe some difficulties which we have encountered and suggest some potential problems that we did not discuss in the main text.

S2.7.1. Length and width of a patch in shape design

Besides the 4-patch design in the shape code system, we have tried other designs with higher complexity (6-patch and 9-patch systems) that we expected to give higher specificity. But as the number of patches increased, we had to design each patch with less material, yielding patches with a smaller number of helices. The flexibility of DNA, coupled with the strength of the stacking interactions, caused these “narrow-patch” systems to be more vulnerable to bent-patch bonds. Fig. S8 briefly summarizes the two systems.

In the 6-patch design (Fig. S8a) we introduced physical gaps between each adjacent pair of 2-helix patches, to minimize any effect of the electrostatic repulsion. (It seemed possible that electrostatic repulsion between adjacent patches might decrease binding energy. This hypothesis has yet to be adequately tested.) The introduction of physical gaps made the patches narrower and longer, allowing various kinds of bent-patch bonds ($\sim 30\%$ of all bonds) as shown in Fig. S8d,e. Because we used 3 helical turns for each depth increment, the length of the longest protruding patch was 9 helical turns, which is about 30% of the persistence length of double-crossover DNA tiles (~ 30 helical turns, ~ 100 nm) — the most similar structure to the 2-helix patch structure for which the persistence length is known². We chose to use a (6,4,3) shape code so that, in principle, the maximum-strength partial bond would have three active patches (1/2 of the full strength). To our dismay, 5-patch bent-patch bonds formed; if the bending energy were small, these bonds would have a binding energy comparable to that of full 6-patch correct bond.

In the 9-patch system, (without physical gaps and with much shorter patches), a significant fraction of the bonds ($\sim 20\%$) were still bent-patch partial bonds (Fig. S8i,j). We had chosen to use a (9,5,2) shape code so we had expected high binding specificity – the strongest expected incorrect bonds would have a binding energy 2/9 of a full correct bond. To decrease the flexibility of patches, we used a single helical turn for each depth increment, so that the longest protruding patch was just 4 helical turns in length. Thus it was to our further dismay that 8-patch bent-patch bonds formed, which were again potentially very close in energy to full-strength bonds. As a point of interest we note that the 6- and 9-patch systems were not twist-corrected, so the chains in Fig. S8g show the characteristic breaking pattern that is similar to that shown in Fig. 1b of the main text. The global twist might be playing a role in encouraging bent-patch bonds in these systems, but we have not done any experiments to test this possibility.

To decrease flexibility, our final “successful” shape code system employed only four of patches that were 4-helices wide and protruded at most 6 helical turns. Many questions remain: How many patches are optimal for this kind of study? How wide (in terms of number of helices) should each patch be? How long can they be? What is the bending energy of the patches under the buffer condition used? We do not yet have answers to these questions, but it is certain that there is a trade-off between the complexity (and hence the potential specificity in ideal case without helix bending) and the bond reliability. Of course, this problem is limited to “soft” systems like DNA, thus might be avoided in a system with sufficient rigidity.

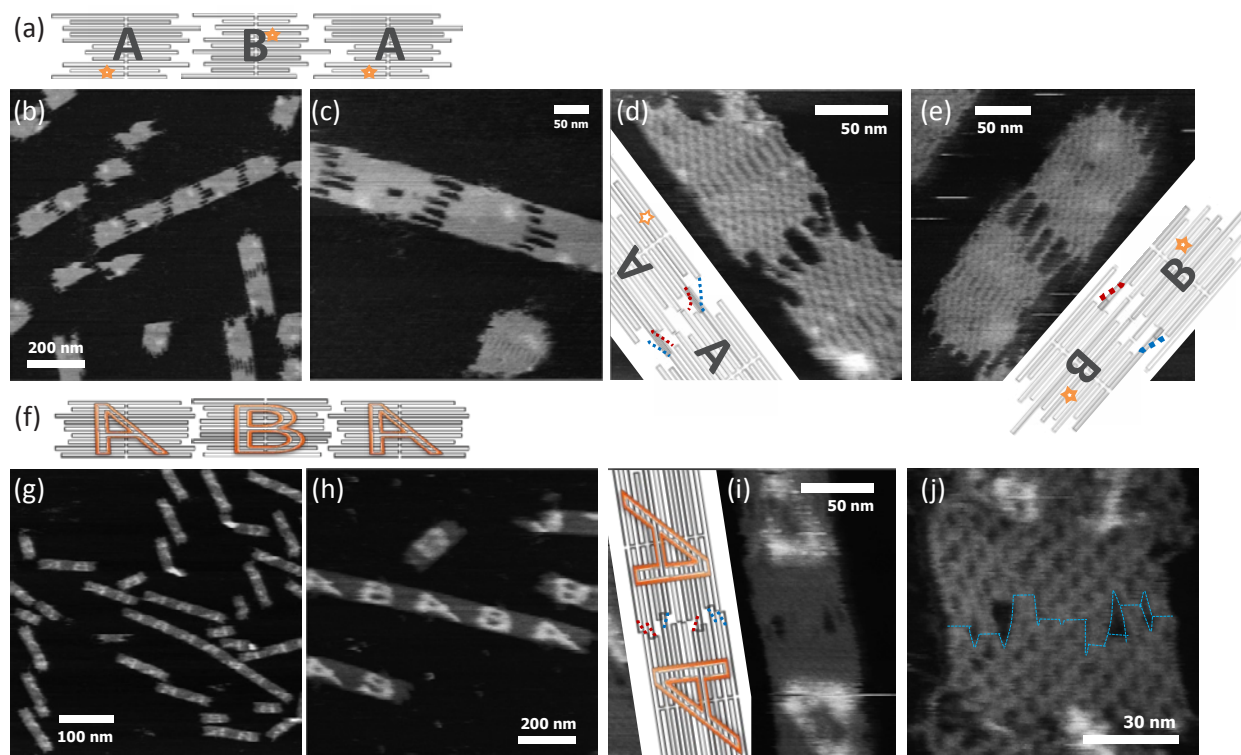

Figure S8. Performance of 6-patch and 9-patch shape-coded systems. (a) Models of the 6-patch system. The edge shapes of the **A** origami and **B** origami were designed such that the origami form continuous alternating **AB** chains. Shape sequences were ‘132120’ for **A-B** bonds and ‘011310’ for **B-A** bonds. Stars indicate the locations of dumbbell hairpins, which serve as topographic labels for AFM. (b) & (c) Typical AFM images of the system that show full-strength correct bonds. (d) & (e) Typical bent-patch bonds which manage to bind via 5 active patches. The red dotted lines on the models depict bent patches coming from the origami on the top, and the blue dotted lines depict bent patches coming from the origami on the bottom. (f) Models of the 9-patch system. Shape sequences were ‘034222043’ for **A-B** bonds and ‘340224301’ for **B-A** bonds. (g) & (h) Typical AFM images. Note that the chains in (g) show the characteristic breaking pattern of the twisted origami chains described in Fig. 1 of the main text. (i) & (j) Typical bent-patch bonds with 8-patch bond strength. The red and blue dotted lines in (i) are used in the same way as in (d) or (e). The narrow blue dotted line in (j) roughly follows the blunt-ends and helical sidewalls of the edge structures.

S2.7.2. Potential interference from the remainder staples

Since the length of the scaffold strand is fixed to be 7249 bases, a DNA origami design that uses fewer than 7249 bases will leave a *remainder* in the form of unfolded single-stranded scaffold – in most designs the remainder takes the form of a single loop. To avoid potential interactions of such a single-stranded remainder on one origami with the remainder of another origami, it is usual to add a set of *remainder staple strands* which have the function of hybridizing to the remainder and turning it into an unreactive double-stranded loop.

When multiple origami which do not share the same underlying design are mixed together, e.g. as in our **A-B-C-D** chains with shape complementarity, there is the possibility of interference between the remainder staple strands of one origami and single-stranded regions of the other origami. In general, a subset of staple strands from one origami may bind single-stranded loopouts on other origami via partial complementarity. (Such loopouts are common in our system because they are used to enforce the ‘GC’ sequence constraint at the blunt ends of helices.) Binding of staple strands to loopouts does not, in general, seem to affect the origami, but in certain cases remainder strands may have complementarity to surrounding scaffold sequence outside of the loopout. In such cases the remainder strands can begin to displace nearby staples. Because the remainder staples are designed to be “continuous” complements to the remainder loop, each successive remainder staple that displaces a regular staple potentially opens up a site for another remainder to bind. Remainder staples may thus sequentially unfold the local structure of another origami. This process may be energetically favorable because the remainder strands make continuous duplex which likely has a lower energy than origami structure (because of its crossovers and twist strain). In some of our initial experiments on shape complementary origami, we experienced this problem: individual origami folded well but when mixed together remainder staples from one origami caused large structural disruptions in other origami. We do not show this data since none of our final designs exhibit the problem.

Two potential solutions exist: (1) One can avoid the use of remainder staples – in most cases single-stranded remainder sections of the scaffold will cause no further problem. (2) One can design the remainder loops of different origami to coincide (have almost the same sequence), so that the remainder staples of one origami will not bind and invade loopouts of another origami. The latter approach was used successfully in our **A-B-C-D** chain system.

S2.7.3. Possible collisions between edge staples

When designing an origami system with uniform edge sequences (e.g. ‘GC’) as in our system, if one takes the same approach as ours – generating loopouts to shift the scaffold sequences – one should note that doing so limits the number of possible edge staple strands. In the 7249-base sequence of the M13mp18 scaffold strand, there are 393 occurrences of ‘GC’ (occurring on average every 18.4 bases, see schematic Fig. S9 below). Hence, ideally, there are 393 different positions at which edge staples can be located. Given a particular geometric design for an origami, one has some choice in terms of which edge staple positions to use; one can change the edge staple sequence at a particular geometric position in the origami by changing the length of the loopouts and/or changing the position at which the scaffold sequence starts in the design. However, when designing multiple origami that are large and use up all the sequence, or further when the origami designs share a similar “start position” for the scaffold sequence (as occurs in our shape-coded **A**, **B**, **C**, **D** system) there is a high probability that some of edge staples from different designs will share subsequences or have identical sequence. For the shape code system we explored this does not cause any difficulties since all edge staple positions are occupied by design. However, in some potential systems (say a hybrid shape code/binary code system) it might be possible for an edge staple present in one origami to fill in an empty edge staple position in another origami and give unexpected results. For example, in some of our initial experiments (not shown) edge staple collisions resulted in unintended aggregation. We note that taking an adapter strand approach to controlling edge sequences (as suggested in the main text) would obviate this problem.

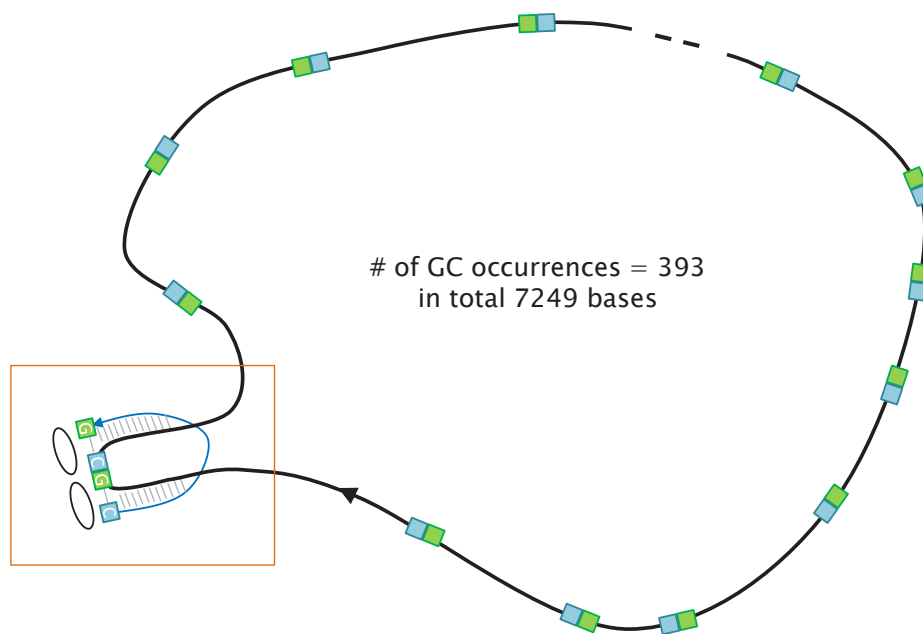

Figure S9. The limited number of ‘GC’ occurrences in the scaffold strand constrains the number of usable edge staple strands. In case of the M13mp18 scaffold strand, with 7249 bases in total, there are 393 occurrences of ‘GC’. The black circular strand represents the scaffold. The boxed area shows how an edge staple strand (blue) binds to the scaffold and forms two ‘GC’ blunt-ends (depicted by ellipses).

Supplementary Note S3: Thermodynamic measurements

The free energy of the stacking bonds was measured by assuming that monomers and dimers of ‘one-sided’ rectangle origami (origami with edge staples on only one side, Fig. S10a) were at equilibrium. The initial monomer concentration equals the total origami concentration, which was assumed to be the initial scaffold concentration (assuming the yield of origami formation was ~100%). The equilibrium concentrations of monomers and dimers were measured by depositing the samples on mica and counting the numbers of each in AFM images (e.g. Fig. S10c). Here the relative ratio of monomers and dimers on surface was assumed to be representative of the ratio in solution. At least two processes could invalidate this assumption: (1) origami dimers might break upon deposition, artifactually elevating the monomers count or (2) origami monomers might land so close to each other that they would be scored as a dimer, artifactually elevating the dimer count. We did not try to estimate the frequency of these processes but we did dilute the origami 5-fold from their formation concentration before depositing them; this decreased the probability of a mismeasurement due to (2). In other experiments dilution was performed on the mica surface, by pipetting a sample onto a 5× larger volume of buffer on the surface. Because origami stick so quickly to mica, this protocol would run the risk of depositing dimers and monomers before they had the chance to equilibrate at the new concentration. To decrease the potential for this effect, sample solutions were pre-diluted, left to equilibrate for ~5 hours (a longer equilibration time, e.g. 10 hours, was tested for the $p=6$ system and did not show a statistically significant difference, so we assumed that a 5 hour equilibration time was long enough for the $p=6$ and weaker bonds), and then deposited without further dilution. (To be completely free from the effects of surface deposition and dilution and to obtain more detailed thermodynamic parameters, e.g. T_m , ΔH , and ΔS , one could alternatively adopt solution-based measurement techniques such as real-time FRET analysis.³)

The free energy of the stacking bonds was calculated as follows. From the counts of monomers M , correct dimers, D , and incorrect dimers (misalignments or other orientations, *other*), and the concentration of origami, $[origami]$, we calculated the monomer concentration, $[M]$, and dimer concentration, $[D]$:

$$[M] = \frac{M [origami]}{M + 2D + 2other} \text{ and } [D] = \frac{D [origami]}{M + 2D + 2other}$$

From $[M]$ and $[D]$ we calculated the equilibrium constant and the free energy of the bond

$$K = \frac{[D]}{[M]^2} \text{ and } \Delta G = -R T \ln K$$

where R is the gas constant (8.314 J/mol·K) and T is the temperature 295 K (22°C).

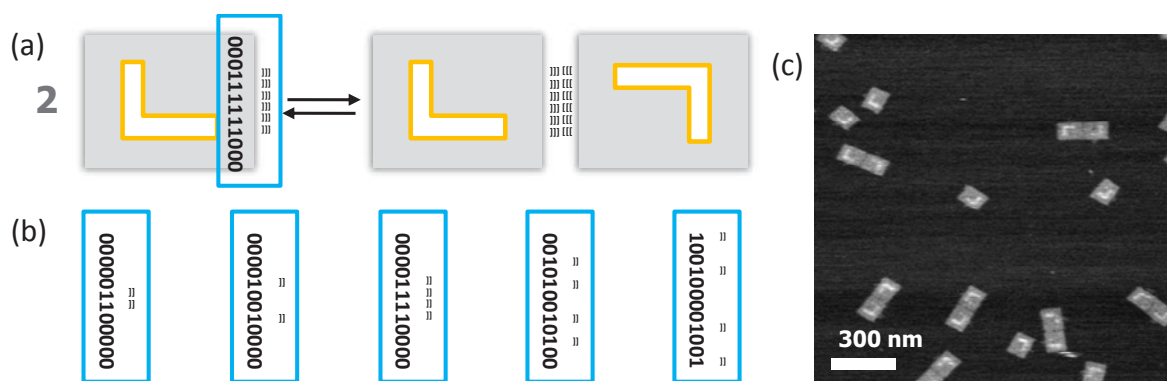

Figure S10. Thermodynamic measurements. (a) Schematic of the monomer/dimer equilibrium for 'one-sided' origami with six active stacking patches in the middle (binary sequence '00011111000'). (b) The number of active stacking patches and their locations were varied as shown and the free energy was measured in each case. (c) A representative AFM image showing the distribution of the monomers and dimers as well as the distribution of bond orientations.

S3.1. First energy model: assuming loop-loop interactions are neutral

We measured the free energy of stacking bonds for various systems with different numbers and sequences of active patches (Fig. S10ab). Assuming that loop-loop interactions have a neutral effect on the free energy of stacking bonds we calculated the free energy per helix for each system (Table S4 and Fig. S11). The total binding energy was expected to be linear in the number of active patches which would imply a constant free energy per helix, yet we observed free energies that varied between -2.67 kcal/mol and -1.42 kcal/mol depending on the system.

A few trends were observed. First, we observed that the magnitude of the binding energy per helix decreased as the number of helices increases. We hypothesize that the resulting sublinearity of binding energy is due to residual large-scale twist (or other deformation) of the origami structure; our picture is that as the number of stacking patches increases and the patches become more spread out, the bending (or twisting) penalty per patch increases. Such residual deformations seem likely to occur because, although twist correction yields a better *average* twist and *decreases* global twist, local twist still differs greatly from 10.4 bp/turn. This hypothesis is compatible with a second observed trend, one within the 4-patch systems. The three 4-patch systems were designed such that one has all its active patches compactly arranged in the middle ('000011110000'), another has its active patches highly spread-out ('100100001001') and the third has active patches with an intermediate spacing ('001010010100'). Dimers in the system with compactly arranged active patches were most stable, while dimers in the system with highly spread-out active patches were least stable; this again suggests a bending or twisting penalty that increases as active patches spread out. Yet, the binding energies for the 2-patch systems did not show a statistically significant difference between the system with most compactly arranged active patches ('000001100000') and the system with more spread-out active patches ('000010010000'). One can imagine that 2-patch systems would be less affected by structural deformations because the bonds are formed by 2-point connections – no matter how much the edge is bent, 2-point connections could be made by rotation of one origami with respect to the other.

Because we hypothesize that non-stacking factors are all destabilizing, we suggest that the average energy obtained for the 2-patch systems, -2.63 kcal/mol ($1\times$ TAE with 12.5 mM Mg^{2+} , 22°C), is most reflective of a pure stacking interaction. One literature value (Ref. 25 of the main text) for the energy of GC/CG stacking is -2.17 kcal/mol (1M Na^+ solution at 37°C). While buffer conditions between the two experiments differ, we did our best to make the measurements comparable by correcting the literature value using temperature-dependent data given in Ref. 25 of the main text. Fig. S12 shows a plot that we reproduced based on experimental data given in Fig. 3a and Supplementary Table 2 of Ref. 25 of the main text. Data were taken for five different temperatures (32°C, 37°C, 42°C, 47°C, and 52°C). Assuming that the temperature dependence of the enthalpy and the entropy of blunt-end stacking is negligible for the given temperature range, it is appropriate to make a linear fit to ΔG_{st} as a function of temperature. A regression line and its equation ($R^2 = 0.8943$) are shown in Fig. S12. Linear extrapolation to the y-axis ($T=22^\circ\text{C}$) gives an energy of -2.42 kcal/mol at 22°C, which is a very close value to the value we obtained.

System ^{&}	binary code	[origami] (nM)	ΔG_{st} (kcal/mol hx)	N (origami count)
2patch-(6,7)	000001100000	0.424	-2.5889	362
2patch-(5,8)	000010010000	0.848*	-2.6738	276
4patch-(5,6,7,8)	000011110000	0.424	-1.7644	178
4patch-(3,5,8,10)	001010010100	0.424	-1.6593	566
4patch-(1,4,9,12)	100100001001	0.424	-1.5578	360
6patch-(4,5,6,7,8,9)	000111111000	0.212 [#]	-1.4223	442

Table S4. Free energy of the stacking bond per helix for various systems.

[&] Numbers in parentheses indicate the locations of active stacking patches (the 1's in the binary sequences).

*A higher concentration was used because it was hard to find dimers for this system.

[#] A lower concentration was used because it was hard to find monomers for this system.

Figure S11. Free energy of the stacking bond per helix for various systems. Energy values per helix vary depending on the number of patches, indicating a nonlinear relationship between the stacking energy and the number of helices. The overall trend (decreasing $|\Delta G_{st}|$ as the number of patches increases) suggests that patches farther away from the middle of the edge must bend more (to counter some remnant global deformation) to bind; this hypothesis is consistent with the trend within the 4-patch systems. The binding energies for the 2-patch systems did not show a statistically significant difference (the error bars partially overlap.) Error bars indicate standard error, obtained by bootstrapping the count data and propagating errors through the equations.

Figure S12. Temperature dependence of the stacking free energy (data taken from Ref. 25 of the main text). A linear fit and its extrapolation gives a stacking free energy of -2.42 kcal/mol at 22°C, which is very close to the value we obtained, -2.63 kcal/mol, at the same temperature.

S3.2. Second energy model: fitting with non-zero loop-loop interactions

In the previous energy model, we assumed that loop-loop interactions are negligible. Here we take an alternate approach and assume that loop-loop interactions are not necessarily neutral and further that they may have some constant free energy value, ΔG_{ll} , either positive or negative. This assumption is somewhat simplistic: if loop-loop interactions are attractive due to unintended base-pairing or base-stacking then the attraction is likely to be highly sequence-dependent, and hence different between different pairs of loops. We also assume that the stacking free energy is a linear function of both the number of active patches (each contributing $\Delta G_p = 2\Delta G_{st}$) and the number of inactive patches (each contributing ΔG_{ll}). For simplicity, for a given p , we averaged the measured free energies for different arrangements of active patches. This resulted in a single free energy for each of three values of p (2, 4, and 6) which allowed us to write the following three equations:

$$\begin{aligned} (1) \quad & 2\Delta G_p + 10\Delta G_{ll} = -10.53 \\ (2) \quad & 4\Delta G_p + 8\Delta G_{ll} = -13.28 \\ (3) \quad & 6\Delta G_p + 6\Delta G_{ll} = -17.07 \end{aligned}$$

(all in kcal/mol)

Here we have more equations than unknowns. In principle, for this system of linear equations to be consistent, the intersection of each pair of equations should coincide exactly. In practice, because of experimental error and potential sequence-dependent effects, we expect that the intersections should lie in close proximity to each other. Fig. S13 shows a plot of the three equations. The intersections occur at $(\Delta G_p, \Delta G_{ll}) = (-2.03, -0.65)$, $(-2.24, -0.60)$, and $(-2.37, -0.48)$, for equations (1) and (2), equations (1) and (3), and equations (2) and (3), respectively. Least squares analysis gives a solution of $(\Delta G_p, \Delta G_{ll}) = (-2.23, -0.59)$ with a root mean square error of 0.24 (which can be roughly interpreted as the average distance of the solution from each intersection in the plot of ΔG_{ll} vs. ΔG_p).

Thus we find that the average free energy of loop-loop interactions (ΔG_{ll}) is negative (suggesting that loop-loop interactions contribute favorably to the binding) but small—less than half the average free energy of a single base pair, -1.41 kcal/mol (nearest neighbor model – Ref. 28 of the main text). It would be interesting to ask whether the average loop-loop interaction is typical, or whether most loop-loop interactions are neutral and just a few inactive patches contribute most of the binding energy. Answering this question will require more experiments, in particular measurements of the binding energy for stacking bonds that have the same stacking sequence, but loops of different base sequence. Another observation is that ΔG_{ll} , the binding energy of a pair of inactive patches, is one-fourth the free energy for an active patch ΔG_p . Its effect on stacking bond strength will depend not just on this ratio, but the number of inactive patches used. For a 16-patch stacking sequence with 7 active patches, the 9 inactive patches will make a contribution to the binding energy that is roughly equivalent to two active patches, and about one-fourth (coincidentally) of the total free energy of the bond. With respect to predicting the ratios of correct vs. incorrect bonds, the contribution of loop-blunt end interactions (which occur frequently in mismatch incorrect bonds) will likely have to be included; so far we have no quantitative data that address such interactions. Finally, we observe that if this model is correct then we must reconcile the relatively small $|\Delta G_{st}|$ observed (1.12 kcal/mol) with much higher literature values (2.42 kcal/mol). It may be partially due to the difference in measurement methods, or it might suggest that the near-B-form stacks

(Note S2.5) which occur in 'relaxed' edges do, in fact, have a somewhat smaller free energy. Future experiments using 'crossover-free' edges may address this question.

Figure S13. Plots of the three equations given for ΔG_p and ΔG_{II} in Note S3.2. Least squares analysis gives a solution of $(\Delta G_p, \Delta G_{II}) = (-2.23, -0.59)$ with a root mean square error of 0.24. Inset shows a zoom-in view of the plot near the intersections of the three lines.

Supplementary Note S4: Additional AFM Data**S4.1. Stacking of rectangles (figure caption on next page)**

Figure S14. Wide-field AFM images of rectangle origami systems. (a-c) Twist-corrected origami with relaxed edges. Note that they form chains with lengths on the order of ~ 10 μm . Chains formed by these origami break in a way that suggests that the breakage occurs upon deposition since pieces lie close to each other. However, in contrast to the twisted origami shown in (d-i), twist-corrected origami break into long pieces and show no preferred direction for the shift between neighboring pieces. Note also that twist-corrected relaxed chains are straight with very rare dislocations, as opposed to the twist-corrected origami with stressed edges shown in (j-o). (d-i) Twisted origami (with relaxed edges). Chains break with a characteristic periodicity (2-6 origami) and directional offset. Note that some parts of the chains seem to unwind while depositing, especially near the ends (as suggested by the straight sections near the ends of twisted chains). (j-o) Origami with stressed edges (with twist-correction). Bonds are promiscuous: many dislocations occur and the bond orientations are random. Orange boxes and arrows show zoom-in areas. Scale bars in (a), (c), (j), (l), (m), (o) are 600 nm, and scale bars in (b), (d-i), (k), (n) are 1 μm .

S4.2. 5-origami chains with orthogonal binary-coded bonds

Figure S15. Wide-field AFM images of 5-origami chains with orthogonal bonds based on a binary code. Full correct bonds between each pair of origami resulted in chains with five distinct origami. Due to mismatched bonds and small stoichiometric discrepancies, shorter chains, longer chains, and 5-origami chains containing incorrect bonds were also found. 88% of total bonds analyzed (N=66) were correct bonds, and the fraction of origami found in 5-origami chains was 31% (N=192). Scale bars, 500 nm.

S4.3. Origami dimers and chains with orthogonal shape-coded bonds

Figure S16. Wide-field AFM images of dimers and 4-origami chains with orthogonal bonds based on a shape code. (a-c) AFM of dimers of (a) $A_r + lB$, (b) $B_r + lC$, and (c) $C_r + lD$, respectively, show high yields of correct, full bonds. The fractions of correct bonds out of total bonds analyzed were 95% (N=191), 98% (N=203), and 97% (N=179), respectively, and the fractions of origami found in correct dimers were 91% (N=397), 90% (N=442), and 91% (N=384), respectively. (d) AFM of the **A-B-C-D** system show 4-origami chains with full, correct bonds (some chains shown are folded), and some shorter chains that may result from stoichiometric discrepancies or mismatched bonds. 81% of total bonds analyzed (N=279) were correct bonds, and the fraction of origami found in 4-origami chains was 44% (N=430). Scale bars, 200 nm.

Diagram for rectangle with 10.44 bp/turn

with positions of dumbbells (orange circles) and positions and lengths of loopouts (black circles with numbers) indicated

Sequence diagram for rectangle with 10.44 bp/turn – (1) with edge staples that create *relaxed edges*

Sequence diagram for rectangle with 10.44 bp/turn – (2) with edge staples that create *stressed edges* (Only the edge staples are different.)

S5.2. Rectangle with 10.67 bp/turn

Positions of dumbbells are indicated by the red-colored staple strands (28-nt dumbbell hairpin sequences are inserted in the middle of each staple strand. See sequence list.)

S5.5. "B" origami

Table with 2 columns: Core Seq name and Sequence. Contains a long list of sequence identifiers and their corresponding nucleotide sequences.

Table with 2 columns: Index and Sequence. Contains a long list of sequence identifiers and their corresponding nucleotide sequences.

Right Edge

Table with 2 columns: Index and Sequence. Contains a list of sequence identifiers and their corresponding nucleotide sequences for the right edge.

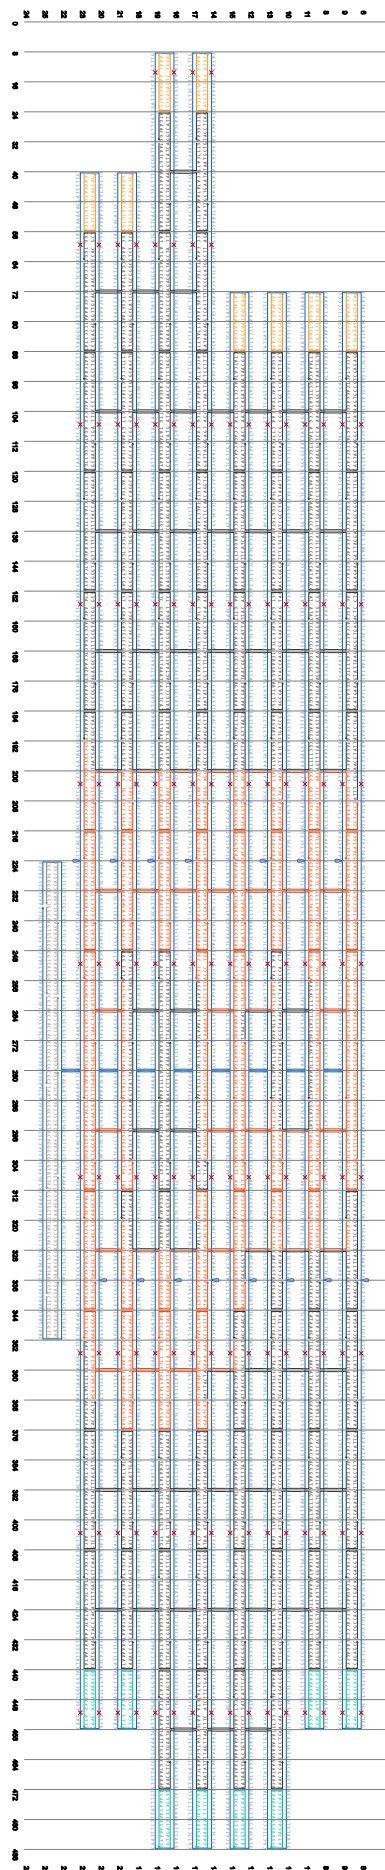

Left Edge

Table with 2 columns: Index and Sequence. Contains a list of sequence identifiers and their corresponding nucleotide sequences for the left edge.

Hairpin-labeled staples (hairpin sequence in lowercase)

Table with 2 columns: Index and Sequence. Contains a long list of sequence identifiers and their corresponding nucleotide sequences for hairpin-labeled staples.

Positions of dumbbells are indicated by the red-colored staple strands (28-nt dumbbell hairpin sequences are inserted in the middle of each staple strand. See sequence list.)
